1 **ABSTRACT**

2 There is an urgent need for development of better diagnostic strategies to improve outcomes
3 in patients with invasive pulmonary aspergillosis (IPA). We hypothesized that lung perfusion
4 single-photon emission computed tomography (SPECT) may be more sensitive and specific
5 than computed tomography (CT) of the chest for detection of IPA because it is an
6 angioinvasive pulmonary infection with characteristics that are different from those of
7 bacterial pneumonia. We used SPECT with injection of technetium-99m-labeled
8 macroaggregated albumin ($[^{99m}\text{Tc}]\text{MAA}$) to measure pulmonary perfusion in non-infected
9 mice, mice with IPA, and mice with bacterial pneumonia. Histopathologic analysis was
10 performed to evaluate the correlation between the perfusion defect and mold invasion. We
11 also attempted to quantitatively evaluate the SPECT images to identify differences in
12 decreased perfusion levels in affected areas in the mouse lung. Histopathologic analysis in the
13 IPA mouse model showed a clear match between areas with a perfusion defect and the
14 presence of mold, indicating that the location of the perfusion defect on a SPECT image
15 reflects angioinvasion of the mold in the lungs. Some of these perfusion defects could be seen
16 before appearance of the infiltrate of CT images. Quantitative analysis confirmed that
17 perfusion in the affected areas was significantly decreased in the IPA model but not in the
18 bacterial pneumonia model ($P < 0.0001$). This imaging method may be preferable to the
19 alternative methods presently used to identify the presence of mold in a patient's lungs.

20

1 **Introduction**

2 Invasive pulmonary aspergillosis (IPA) is an opportunistic fungal infection caused by
3 *Aspergillus* species. It is particularly common in patients with hematologic diseases and is
4 often life-threatening in an immunocompromised host ¹. Despite treatment with currently
5 available antifungal agents, the mortality of invasive aspergillosis reportedly remains as high
6 as 30%–100% ². Therefore, there is an urgent need for development of better diagnostic
7 strategies to improve the outcomes of this disease.

8 Early and accurate diagnosis of IPA, which is critical for better outcomes, remains a
9 challenge. The diagnosis currently relies on culture methods, histopathology, and detection of
10 diagnostic biomarkers (e.g., galactomannan and (1-3)- β -d-glucan) in serum or
11 bronchoalveolar lavage fluid ³. However, these procedures lack both sensitivity and
12 specificity and can delay diagnosis. Further, invasive procedures cannot be used in patients
13 who are seriously ill ⁴.

14 IPA is an angioinvasive pulmonary infection with characteristics that are different from those
15 of bacterial pneumonia in spite of a similar clinical presentation and the infiltrates seen on
16 computed tomography (CT) images. The initial findings typically include nodules with
17 surrounding ground-glass opacities (i.e., the halo sign), which means hemorrhage in the area
18 surrounding the fungus caused by invasion of the vasculature by *Aspergillus* hyphae ⁵. The
19 presence of halo sign allow the preemptive identification of IPA cases even before
20 performing serum galactomannan test ⁶. However, the halo sign is not specific for IPA, so is
21 not considered to be definitive evidence of the disease ⁷.

22 Recently, Stanzani et al. suggested a potential role for CT pulmonary angiography in
23 distinguishing between angioinvasive mold infection and other causes of pulmonary
24 infiltrates, given its ability to detect angioinvasion ⁸. Further, they observed that vessel

1 occlusion detected by CT pulmonary angiography was more sensitive than appearance of the
2 halo sign. Although the number of patients in their study was small and the risk of
3 nephrotoxicity associated with use of an intravenous contrast agent has not been adequately
4 evaluated, their findings suggested that detection of angioinvasion would be an ideal way of
5 identifying a focus of IPA in a patient's lungs earlier than would be possible using other
6 clinical indicators.

7 Imaging modalities other than CT pulmonary angiography, such as single-photon emission
8 computed tomography (SPECT), positron emission tomography (PET), and magnetic
9 resonance imaging (MRI), can also be used for quantitative imaging of regional pulmonary
10 perfusion ⁹. SPECT in particular has several significant advantages. The technique most
11 widely used when measuring pulmonary perfusion by SPECT involves injection of
12 technetium-99m-labeled macroaggregated albumin ([^{99m}Tc]MAA). These particles are 10–
13 150 µm in size and become lodged in the pulmonary capillaries at a rate that is proportional
14 to local blood flow. Identification of the number of pulmonary capillaries destroyed by
15 microinvasion of *Aspergillus* hyphae is necessary to be able to detect IPA in its early stages.
16 Lung perfusion SPECT may be better able to identify IPA in its early stages than other
17 modalities.

18 Several studies have attempted to develop a method to identify the localization of *Aspergillus*
19 in the body. Petrik et al. reported that administration of ⁶⁸Ga-labeled siderophores, which are
20 ferric ion-specific chelators, showed high uptake, specifically by *A. fumigatus* in vitro and in
21 vivo, and therefore, could be used for PET imaging ¹⁰. Wang et al. used ^{99m}Tc-labeled 28S
22 fungal rRNA-targeted morpholino oligomer probes for in vivo SPECT imaging ¹¹. Recently,
23 Rolle et al. developed a probe, [⁶⁴Cu]DOTA-labeled *A. fumigatus*-specific monoclonal
24 antibody, and conducted in vivo antibody-guided PET and MRI ¹². These methods can aid the

1 direct visualization of locations of molds in the lungs, and their characteristics are ideal for
2 the detection of IPA lesion. However, the safety of these experimental probes in humans has
3 not been confirmed, and moreover, its use in routine clinical settings may be extremely
4 expensive. A well-balanced usefulness and ease of access is important to familiarize the
5 general population to these diagnostic modalities. Compared to these methods, lung perfusion
6 SPECT is already well-established in routine clinical practice, is widely available, and is
7 relatively inexpensive⁹.

8 We hypothesized that lung perfusion SPECT may be more sensitive and specific than chest
9 CT in its ability to detect IPA. In this study, lung perfusion SPECT/CT images of IPA and
10 bacterial pneumonia were investigated in a mouse model to confirm our hypothesis.

11

12 **Methods**

13 *Animals*

14 Female ICR mice aged 6–8 weeks were purchased from Japan SLC, Inc. (Shizuoka, Japan).
15 The animals were kept under standardized and sterile environmental conditions (room
16 temperature 24°C, relative humidity 50%) on a 12-h light-dark cycle and received food and
17 water ad libitum. All the animal experiments were performed in accordance with the
18 recommendations in the Fundamental Guidelines for Proper Conduct of Animal Experiment
19 and Related Activities in Academic Research Institutions under the jurisdiction of the
20 Ministry of Education, Culture, Sports, Science and Technology. All experimental procedures
21 were approved by the Institutional Animal Care and Use Committee of Nagasaki University
22 (approval number 1408191168).

23 *Mouse Model of IPA*

24 The clinical isolate used in this experiment was *Aspergillus fumigatus* MF367, which was

1 obtained from the Pneumology Department of Nagasaki University Hospital, Nagasaki, Japan
2 ¹³. The fungus was grown on potato dextrose agar at 35°C until good sporulation was
3 obtained. Conidia were harvested by flushing with sterile saline and subsequent filtering
4 through a cell strainer with a pore size of 40 µm.

5 An intraperitoneal injection of cyclophosphamide (Sigma-Aldrich, St Louis, MO, USA; 150
6 mg/kg) was administered on day -3 and day 0 to render the animals neutropenic by day 5. On
7 day 0, the mice were anesthetized by an intraperitoneal injection of medetomidine (Kyoritsu
8 Seiyaku Corporation, Tokyo, Japan; 0.3 mg/kg), midazolam (Sandoz, Holzkirchen, Germany;
9 4.0 mg/kg), and butorphanol (Meiji Seika Pharma Co. Ltd., Tokyo, Japan; 5.0 mg/kg). The
10 animals were then inoculated with 5×10^6 conidia of *A. fumigatus* MF367 via intratracheal
11 injection ¹⁴. Fifteen mice were sacrificed on days 4, 8, and 15 (five mice per group) to
12 confirm that infection was successful. The lungs of these mice were collected in tubes with 1
13 mL of sterile saline and homogenized. Next, 100 µL of the cell suspensions were plated in
14 10-fold dilution steps on potato dextrose agar. The number of colony-forming units (CFU)
15 were counted after 24–48 h of incubation at 35°C.

16 *Mouse Model of Bacterial Pneumonia*

17 A mouse model of bacterial pneumonia caused by the *Klebsiella pneumoniae* KEN-11 strain
18 was used because of its good repeatability ¹⁵. To prepare the inocula, a single colony of KEN-
19 11 was incubated in Luria-Bertani broth at 37°C for 24 h with shaking at 250 rpm. ICR mice
20 were intratracheally infected with the bacterial suspension (1×10^4 CFU/mouse) under
21 general anesthesia using the method described above for the IPA model. No
22 immunosuppression was needed for this model.

23 *Ex Vivo Study*

1 On comparison of lung perfusion SPECT images with pathologic findings, we realized that it
2 would be impossible to compare SPECT images of living mice with pathologic images
3 directly because the lungs collapsed and changed in shape when they were removed from the
4 body. Therefore, we performed an ex vivo study as described below.

5 Approximately 80 MBq of [^{99m}Tc]MAA were administered via the tail vein on day 4 to mice
6 infected with IPA (n = 5) and on day 3 to mice infected with bacterial pneumonia (n = 5). Ten
7 minutes following the injection, the mice were sacrificed and the heart and both lungs were
8 collected. The heart was not separated from the lungs to avoid dislodging [^{99m}Tc]MAA from
9 the pulmonary capillaries. The organs were laid flat between sponges in labeled cassettes.
10 The cassettes were then imaged using a Triumph combined PET/SPECT/CT system (TriFoil
11 Imaging, Chatsworth, CA, USA). After imaging, the cassettes were fixed for processing,
12 embedding, and sectioning. Tissue slices were stained with hematoxylin-eosin and Grocott's
13 methenamine silver using standard procedures.

14

15 *Imaging*

16 The infected mice were imaged using the Triumph combined PET/SPECT/CT system. The
17 SPECT images were acquired using a four-head gamma camera equipped with single pin-
18 hole collimators (diameter 1.0 mm, focal length 90 mm). The experimental mice were
19 injected in vivo with approximately 50 MBq of [^{99m}Tc]MAA via the tail vein. Immediately
20 post-injection, the mice were anesthetized with isoflurane 1.5%. Approximately 5 minutes
21 later, SPECT data were acquired for 21 minutes using the following imaging parameters: 20
22 s/projection, 64 projections over 360° in 5.6° increments, and a 40-mm radius of rotation.
23 The CT images (X-ray source 75 kVp, 230 μA, 128 projections over 360°) were acquired
24 after the SPECT images, with each animal in exactly the same position. All imaging work

1 was completed in the Radioisotope Research Center at Nagasaki University.

2 *Analysis of SPECT/CT Images*

3 The SPECT data were reconstructed using a three-dimensional (3D) maximum likelihood
4 expectation maximization algorithm (50 iterations). The acquired SPECT and CT data were
5 processed using the medical imaging data examiner tool in the AMIDE software package and
6 OsiriX MD (Pixmeo, Geneva, Switzerland).

7 The SPECT images were quantitatively evaluated for 3D total lung volume and for the two-
8 dimensional (2D) target lung area. For 2D analysis, we used maximum counts in the target
9 region of interest (ROI) because most regions in a lung field include normal defects in the
10 small pulmonary arterioles and capillary beds (e.g., the hilum of the lung, bronchus, and large
11 vessels). A background ROI was also drawn in reference tissue that was outside the lung and
12 presumed to be normal. The target-to-background ratio (TBR) was then calculated. For each
13 2D area, three TBR values (a target area and slices immediately above and below) were
14 calculated. The mean TBR was calculated for each area. We compared the TBR value for the
15 3D total lung volume and that of the 2D affected area, defined as an area with an infiltrate on
16 the CT image, for sequential changes from day 1 to day 5.

17 Mice in the two groups were compared to detect differences in decreasing perfusion levels in
18 an affected area between lung tissue with IPA and that with bacterial pneumonia. The mean
19 decrease (and the standard deviation) was calculated from the differences in TBR between
20 areas with and without infiltrates on CT images in the lungs of mice in the IPA group (n = 10)
21 and those in the bacterial pneumonia group (n = 5).

22 *Statistical Analysis*

23 Statistical significance was determined using the paired *t*-test. All tests were two-tailed, and a

1 *P*-value < 0.05 was considered statistically significant. The statistical analysis was performed
2 using GraphPad Prism version 6.0 (GraphPad Software Inc., San Diego, CA, USA).

3

4 **Results**

5 *Perfusion Defects in SPECT Images Indicate Angioinvasion by A. fumigatus*

6 In this IPA mouse model, neutropenia (< 500 cells/ μ l) persisted to around day 5 and
7 recovered after day 7. Therefore mice recovered from IPA after day 7. Before analysis of the
8 perfusion SPECT images for the IPA mouse model, we confirmed the presence of *Aspergillus*
9 in the lungs of the mice used in the study. The mean fungal burden (CFU/lung) was 1.1×10^3
10 $\pm 1.1 \times 10^3$ (day 4), $1.6 \times 10^1 \pm 1.5 \times 10^1$ (day 7), and $6.0 \times 10^0 \pm 1.3 \times 10^1$ (day 14),
11 respectively (five mice per group). The fungal burden was highest on day 4 and gradually
12 decreased from day 7 to day 14. A few *Aspergilli* remained in the lungs on day 14.

13 Lung perfusion SPECT with [^{99m}Tc]MAA in the normal mice provided clear images of the
14 functional capillary beds in the lungs. Normal defects were seen, such as those in the hilum
15 of the lung, bronchus, and large vessels, none of which contain small pulmonary arterioles. In
16 the IPA mouse model, we found local abnormal defects in the lungs. Histopathologic analysis
17 revealed inflammation, microvascular hemorrhage, and pulmonary alveolar edema in affected
18 lung areas in the IPA mouse model on day 4 after infection (Fig. 1A, 1D). No necrotic areas
19 were found on day 4 in the lungs of the mice used in this model, which suggests that the
20 SPECT images in the ex vivo study were able to show IPA at a very early stage. We also
21 confirmed that absence of lung perfusion on day 4 was not attributable to a necrotic change in
22 the lung tissue. Images stained with Grocott's methenamine silver showed the elongated
23 hyphal structures of the mold in the affected area (Fig. 1B, 1E). The pathologic analysis
24 revealed micro-angioinvasion by *A. fumigatus* in affected areas. Other possible causes of

1 impaired pulmonary blood flow, such as pulmonary artery occlusion by *A. fumigatus*, were
2 not observed.

3 A 2D perfusion SPECT image was reconstructed using the same slice as that used for
4 pathologic analysis (Fig. 1C). The outline of the lungs seen on the perfusion SPECT image
5 clearly matched that of the lung specimen. The same normal perfusion defects seen in the
6 large pulmonary vessels and bronchus were detected on the in vivo images. We confirmed a
7 local lung perfusion defect in the IPA mouse model, which could not be considered a normal
8 defect because it included an area outside of the large vessels and bronchus (Fig. 1A, 1C).
9 Further, there was a clear match between the perfusion defect area and the presence of *A.*
10 *fumigatus* (Fig. 1B, 1C). The same results were obtained for all mice in the IPA model. These
11 findings suggest that the perfusion defects identified on a SPECT image represent
12 angioinvasion of *A. fumigatus* in the lungs and that the exact location of *A. fumigatus* can be
13 determined during the early phase of IPA.

14 *Sequential Changes on CT and perfusion-SPECT Images in an IPA Mouse Model*

15 Physicians usually rely on chest radiographs and CT images to identify the location of mold
16 infection in patients with suspected IPA. The sequential changes seen in our IPA mouse
17 model were confirmed on CT images (Fig. 2). Most of the mice in this model showed no
18 infiltrates on day 1 despite the presence of mold in their lungs. The infiltrates appeared from
19 around day 5 after infection and persisted to around day 8, albeit with a slight reduction in
20 density. The infiltrates had almost disappeared by approximately day 15, despite a few
21 Aspergilli remaining. The sequential changes on perfusion SPECT images were also
22 confirmed on CT images taken at the same times with the same positioning (Fig. 2). The
23 same lesions that showed infiltrates on CT images also showed perfusion defects on the
24 SPECT images. These perfusion defects persisted at around day 14 despite disappearance of

1 the infiltrate, indicating the possibility of residual *Aspergillus*, which would be consistent
2 with the culture results showing some remaining *Aspergillus* at this time. Quantitative
3 evaluation of the SPECT images on days 1 and 5 for the same mouse shown in Fig. 2
4 revealed a significant decrease in the TBR in the affected area, but did not show a significant
5 decrease in 3D total lung volume (Fig. 3).

6 In some mice, we found abnormal areas with perfusion defects but no infiltrates on the CT
7 images. Some of these perfusion defects appeared on day 1 and infiltrates subsequently
8 appeared on day 5 in the same area (Fig. 4). However, we could not directly confirm the
9 presence of mold at sites of perfusion defects without infiltrates because the lungs collapsed
10 and changed in shape when they were removed from the body. These findings indicate that
11 sites of IPA infection may be detected earlier on SPECT images than on CT images.

12 *Perfusion SPECT Could Distinguish IPA From Bacterial Pneumonia*

13 The ability to discriminate IPA from other types of pneumonia that could show similar
14 infiltrates on CT images is important for selection of appropriate treatment. Therefore, we
15 also performed CT and perfusion SPECT examinations in a mouse model of bacterial
16 pneumonia. The pulmonary infiltrates seen on CT images on day 4 after infection in the IPA
17 mouse model were also seen in the mouse model of bacterial pneumonia (Fig. 5A). It was
18 impossible to distinguish between bacterial pneumonia and IPA on the CT images because the
19 characteristics of the infiltrates were too similar.

20 We also assessed the ability of SPECT perfusion images to distinguish between bacterial
21 pneumonia and IPA. Unlike the mice with IPA, most of the mice with bacterial pneumonia
22 showed only a minor decrease in perfusion on SPECT images (Fig. 5A). A perfusion defect
23 was detected in one of the mice in the ex vivo bacterial pneumonia study; however, this
24 mouse had developed extremely severe pneumonia, so the defect was attributed to necrotic

1 changes in the lung. Most mice showed only a very slight decrease in perfusion similar to that
2 in the in vivo study.

3 We also attempted to distinguish between IPA and bacterial pneumonia using differences in
4 the TBR between an affected area and a normal area. TBR values could decrease for several
5 reasons, including a reduction in the amount of [^{99m}Tc]MAA injected, so we did not directly
6 compare these values between the lesions and instead compared them between areas with and
7 without infiltrates. The difference in TBR between affected areas and normal areas was
8 statistically significant (32.4 ± 5.6 for IPA [n = 10] and 7.1 ± 6.3 for bacterial pneumonia [n =
9 5]; $P < 0.0001$; Fig. 5B), indicating that perfusion in an affected area was significantly lower
10 than that in a normal area in mice with IPA but not in mice with bacterial pneumonia.

11

12 **Discussion**

13 *Aspergillus* spp. are the causative organisms for IPA, which is associated with high morbidity
14 and mortality, especially in allogeneic hematopoietic stem cell transplant recipients and
15 patients with hematologic malignancies. When the spores are inhaled by patients who are
16 neutropenic, they germinate and the hyphae invade the tissues¹⁶. *Aspergillus* spp. also invade
17 and occlude the blood vessels, causing thrombosis and tissue infarction. Development of a
18 method that can evaluate the blood vessels in the lung could allow earlier diagnosis of
19 angioinvasive pulmonary mold disease¹⁷. Micro-angioinvasion would occur before tissue
20 infarction, so a method that can evaluate micro-pulmonary perfusion could detect IPA earlier
21 than CT pulmonary angiography. In this study, we demonstrated that perfusion SPECT with
22 [^{99m}Tc]MAA could detect micro-angioinvasion by mold, so this well-established method has
23 potential for earlier diagnosis of IPA. Moreover, compared with CT pulmonary angiography,
24 perfusion SPECT should also be better able to detect infarcted lung tissue in patients with IPA

1 because it is also an established method for diagnosis of pulmonary infarction ¹⁸.
2 Unfortunately, this could not be investigated in our IPA mouse model because the mice had
3 already succumbed to IPA before infarction could develop. However, clear perfusion defects
4 attributable to tissue necrosis were seen in the mouse model of bacterial pneumonia, which
5 suggests that impaired pulmonary blood flow could be detected by this method.

6 In this study, we showed two potential benefits of perfusion SPECT with [^{99m}Tc]MAA for
7 detection of IPA. First is the potential for perfusion SPECT to detect IPA earlier than CT
8 imaging, which is important considering that the earliest findings in patients with IPA at
9 present are abnormalities on CT imaging. Despite the resolution of the preclinical SPECT
10 system used in this study is much lower than CT, perfusion SPECT could detect the IPA
11 infection early phase, as described in results. This is the evidence that perfusion SPECT has a
12 very high sensitivity to IPA infection. The earlier treatment is started in these patients, the
13 better the prognosis, so earlier diagnosis of IPA using perfusion SPECT might improve the
14 outcomes of treatment ¹⁹. Clinical trials are now needed to confirm that perfusion SPECT can
15 detect IPA earlier than CT. Perfusion SPECT is already widely used in routine clinical
16 practice and can be put to further practical use if physicians can agree on when perfusion
17 SPECT should be considered in patients with suspected IPA. Second, we found that if a
18 perfusion defect was present, it persisted on the CT images in spite of improvement with
19 regard to the infiltrate. The clinical significance of such persistent defects is still not clear.
20 However, given that we were able to confirm persistence of a perfusion defect and mold in
21 the lungs of mice with IPA at the same time, it is possible that perfusion SPECT could help to
22 guide decisions with regard to cessation of antifungal treatment. Unfortunately, we were not
23 able to analyze the relationship between lung infiltrates, perfusion defects, and presence of
24 mold in the lungs directly by invasive methods such as pathologic or culture analysis. The
25 main reasons for this were that non-invasive CT imaging was required in the same mice over

1 time in this sequential imaging experiment and that it was impossible to perform CT imaging
2 of lungs that had collapsed and changed in shape after removal from the body.

3 A possible concern regarding perfusion SPECT is its specificity for diagnosis of IPA. There
4 are many clinical causes of impaired pulmonary perfusion, including embolization, infarction,
5 necrosis, destruction of capillaries, and hypoxic pulmonary vasoconstriction. Hypoxic
6 pulmonary vasoconstriction can be caused by any type of pneumonia and also by atelectasis
7 in affected areas ²⁰. Blood flow in affected areas may be decreased to varying degrees
8 depending on the severity of pneumonia. Although IPA and bacterial pneumonia have a
9 similar clinical presentation, bacteria do not directly destroy pulmonary capillaries, whereas
10 mold is angioinvasive, and the difference in extent of the perfusion decrease in the affected
11 area between IPA and bacterial pneumonia was confirmed in our study. This difference
12 indicates that perfusion SPECT can distinguish IPA from bacterial pneumonia and atelectasis,
13 which show a variety of infiltrates on CT images. In addition, we continue to analyze the
14 ability of perfusion SPECT to distinguish mold infection other than aspergillosis such as
15 mucormycosis from IPA.

16 We observed a clear perfusion defect for severe bacterial pneumonia with necrosis in this
17 study. This finding indicates that septic emboli and lung abscess, which are respective
18 manifestations of embolization and tissue necrosis, may show a perfusion defect resembling
19 that found in IPA. However, these differential diagnoses can usually be distinguished by host
20 factors and the results of other examinations.

21 Another significant aspect of this study was that pulmonary perfusion could be quantified by
22 SPECT imaging. Perfusion SPECT has rarely been used to image the lungs of small animals,
23 so a quantitative method for measuring lung perfusion is not established. Generally, average
24 values are often used for data analysis. However, we calculated TBR using the maximum

1 uptake counts in the ROIs in the present study. There are two reasons why it was not
2 reasonable to adopt the average uptake counts to calculate the TBR. First, the ROIs include
3 areas with normal perfusion defects, so lung perfusion is easily underestimated. Second, the
4 distribution of [^{99m}Tc]MAA is not uniform. In using the maximum uptake values, we referred
5 to the idea of maximum of standardized uptake value (SUV_{max}) which widely used for
6 clinical PET examination. TBR calculated from maximum uptake value is little affected by
7 scatter noise, non-uniformity of ^{99m}Tc-MAA, and normal perfusion defects. Thus, TBR
8 allowed successful quantification of lung perfusion without the effects of areas containing
9 normal defects and non-uniform tracer distribution.

10 In conclusion, we have found that lung perfusion SPECT with [^{99m}Tc]MAA can detect micro-
11 angi invasion by *A. fumigatus* in an IPA mouse model, indicating that this imaging technique
12 could be used to identify the presence of the mold in a patient's lungs. This method has
13 several advantages in that it will allow earlier detection of mold invasion, the examination is
14 non-invasive, inexpensive, and without adverse effects for patients, and it is already in
15 routine clinical use. We proceed clinical confirmation of these results in the future.

1 **FIGURE LEGENDS**

2

3 **FIGURE 1.** Histopathologic images and an ex vivo perfusion SPECT image for the same
4 slice of lung in a mouse model of invasive pulmonary aspergillosis on day 4 after infection.
5 (A) Hematoxylin-eosin staining. (B) Grocott's methenamine silver staining. (C) An ex vivo
6 perfusion-SPECT image. (D) High-power field image indicated by a yellow arrow in Fig. 1A.
7 Hematoxylin-eosin staining. (E) High-power field image indicated by a yellow arrow in Fig.
8 1B. Grocott's methenamine silver staining. †Heart. Black bar, 100 μ m. SPECT, single-photon
9 emission computed tomography

10

11 **FIGURE 2.** Sequential changes on CT images and perfusion single-photon emission
12 computed tomographic images of the chest in a mouse with invasive pulmonary aspergillosis.
13 The same lesion clearly appears as a perfusion defect with an infiltrate on the CT image;
14 however, the perfusion defect persisted at around day 14 despite disappearance of the
15 infiltrate (arrows). CT, computed tomography; Perf, perfusion

16

17 **FIGURE 3.** Quantitative evaluation of perfusion single-photon emission computed
18 tomographic images on days 1 and 5 for the same mouse shown in Fig. 2. (A) TBR values for
19 three-dimensional total lung. (B) TBR values for the two-dimensional affected area of the
20 lung. * $P < 0.01$. TBR, target-to-background ratio

21

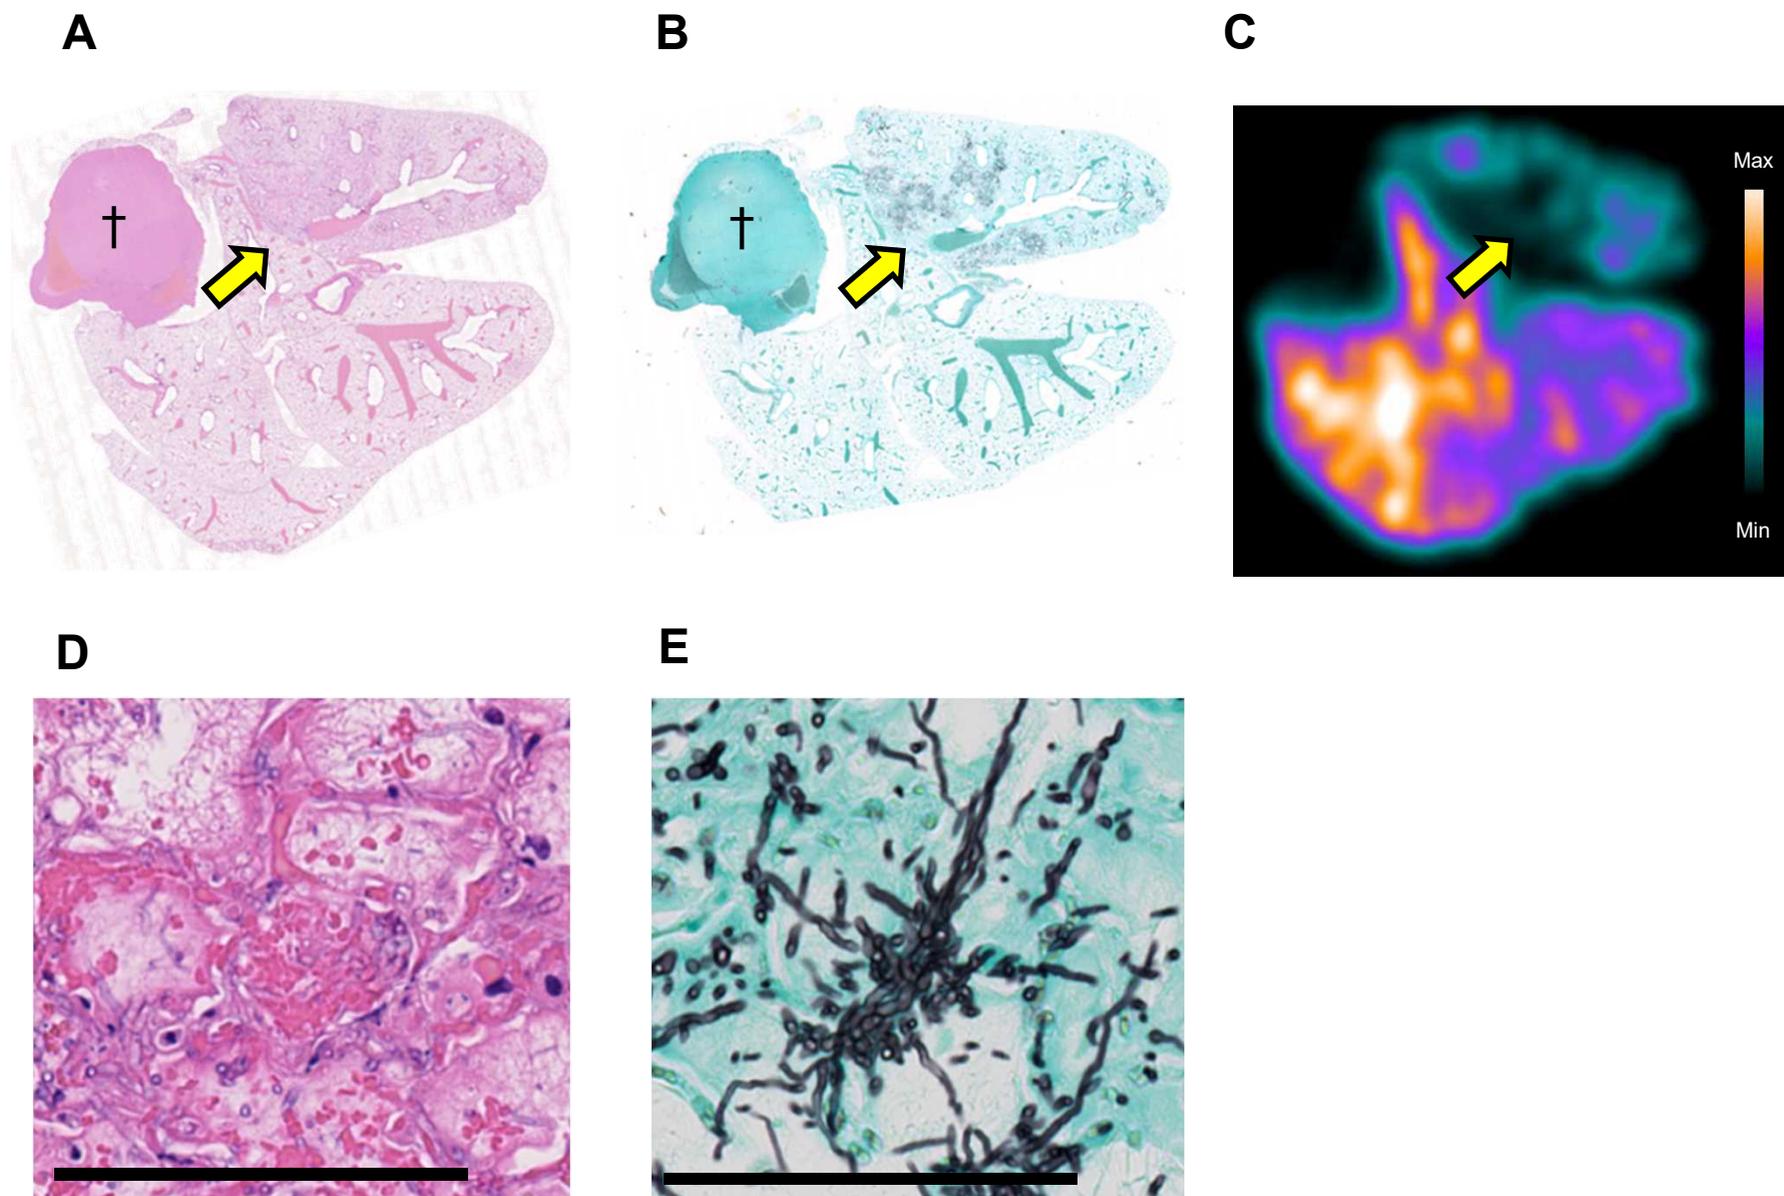

1

2 **FIGURE 4.** An example of a perfusion defect appearing earlier than the infiltrate in a mouse
3 model of invasive pulmonary aspergillosis. The perfusion defect appeared on day 1 (white
4 circle) and the infiltrate subsequently appeared in the same lesion on day 5 (yellow circle).
5 CT, computed tomography; Perf, perfusion

6

7 **FIGURE 5.** Difference between invasive pulmonary aspergillosis and bacterial pneumonia
8 on perfusion SPECT images. (A) The arrow shows an infiltrate on the chest CT image of a
9 mouse with bacterial pneumonia on day 4 after infection, for which there is only a slight
10 decrease in perfusion on the SPECT image. (B) Difference in maximum TBR between
11 affected and non-affected areas in mouse models of invasive pulmonary aspergillosis and
12 bacterial pneumonia. The difference in the TBR between an affected area and a normal area
13 was 32.4 ± 5.6 for invasive pulmonary aspergillosis (n = 10) and 7.1 ± 6.3 for bacterial
14 pneumonia (n = 5). * $P < 0.0001$. CT, computed tomography; SPECT, single-photon emission
15 computed tomography; TBR, target-to-background ratio
