## **Abstract**

This study aims to examine the effects of cystine and theanine (CT), which increases glutathione biosynthesis, on the survival rate and acute radiation injury of the small intestine and bone marrow using a rat model. CT pre-treatment (280mg/kg for 5 days) significantly improved weight loss and survival rate of rats as compared with the control group after 5 Gy. CT pre-treatment significantly increased the rate of mucosa and crypt length, and decreased the number of apoptotic cells, TUNEL and cleaved caspase-3 positive cells, while increasing the number of mitotic cells and Ki-67 positive cells in jejunal crypts and villi compared to control rats post-irradiation. CT also suppressed bone marrow cell loss and reduced the number of apoptotic cells in bone marrow. These results suggest a protective effect of CT pre-treatment for acute injury after irradiation through apoptosis inhibition and increased proliferative activity in jejunal crypt cells and bone marrow cells.

<sup>1</sup>*Keywords:* Cystine and Theanine, Jejunum, Bone marrow, Apoptosis, Radiation

<sup>1</sup> *Abbreviations:* GSH, glutathione; CT, cystine and theanine; ROS, reactive oxygen species; TUNEL, terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nicked labeling; GSSG, glutathione-S-S-glutathione

## **1. Introduction**

Acute intestinal injury and bone marrow suppression are well known as serious, life-threatening effects induced by whole-body high-dose radiation. Hematopoietic syndrome can occur after whole-body irradiation at a dose of 2 Gy or higher, which reduces leukocyte and platelet numbers and causes bone marrow suppression, resulting in death within 30 days of exposure (Kirsch et al., 2010; Mettler and Voelz, 2002). At higher doses of 10 Gy, death occurs within ten days as a result of damage to the gastrointestinal tract (Kirsch et al., 2010; Mason et al., 1989). Exposure to ionizing radiation generates an increase of reactive oxygen species (ROS) (Mikkelsen and Wardman, 2003) and results in rapid apoptosis in bone marrow cells (Singh et al., 2017) and intestinal crypt cells (Potten and Grant, 1998; Potten 2004), which undergo high cell turnover rate. Exposure to high doses of radiation can severely reduce hematopoietic stem cells and bone marrow progenitor cells (Singh et al., 2017). Crypt disturbance results from cell loss by apoptosis and the destruction of the stem cells in the crypts, which are responsible for repopulating the lining (Potten et al., 2009). High doses of ionizing radiation damage intestinal crypt cells, and result in shortening of the mucosal length, as well as functional changes. These deleterious effects, including malabsorption, are seen clinically as acute small bowel reactions. Further pharmacological development is required to protect against the toxicity of ionizing radiation.

It is reported that ionizing radiation-induced cell death is regulated via a p53-dependent pathway in the gastrointestinal tract (Merritt et al., 1997). Caspase-3 activation is a major effector in the apoptotic process following irradiation of intestinal cells and bone marrow cells (Marshman et al., 2001; Segreto et al., 2011). Previously, we have reported that polaprezinc, which is an anti-ulcer agents and a chelating compound consisting of zinc ion and L-carnosine, and basic fibroblast growth factor (bFGF) exert protective effects on radiation-induced apoptosis in the small intestine of rats (Matsuu-Matsuyama et al., 2008; Matsuu-Matsuyama et al., 2010). Both agents could suppress radiation-induced apoptosis and the p53 pathway in intestinal crypt cells at an early stage within 24 h post-irradiation.

Cystine is a sulfur-containing amino acid consisting of two cysteine molecules connected by an S-S bond. Cystine is a precursor of glutathione (GSH), which is responsible for anti-oxidative reactions in the body, and the supply of cysteine is rate-limiting to GSH synthesis (Kurihara et al., 2007). Theanine (gamma-glutamylethylamide), an amino acid found abundantly in green tea, is metabolized to glutamic acid and ethylamine in the intestine or liver (Shibakusa et al., 2012). It has been reported that oral administration of CT enhanced immune function in a mouse surgical model of the small intestine through GSH synthesis (Kurihara et al., 2007, 2013). GSH plays an important role in counteracting oxidative stress induced by ionizing radiations (Mikkelsen and Wardman, 2003; Jagetia, 2007). It is expected that CT exerts protective effects against radiation-induced injury

through an anti-oxidative effect. Patt *et al.* were the first to investigate effects of the amino-acid cysteine in rats exposed to lethal doses of X-rays (800 R) (Patt et al., 1949). It has been reported that cysteine administered orally before LD50/30 total body irradiation (750 R) produced a protective effect against acute radiation effects in mouse splenic lymphocytes (Bari et al., 1968).

In this study, to examine the protective effects of CT against acute radiation-induced injury, we investigated the effects of CT pre-treatment on survival rate after 5 Gy X-ray total body irradiation. We examined the effect of CT pre-treatment on acute radiation injury of rat small intestine and bone marrow, histologically. We then observed the effect of CT on apoptosis, mitosis, and proliferation of small intestinal crypt cells and the apoptosis of bone marrow cells after irradiation.

## **2. Materials and methods**

### **2.1. Animals**

Seven-week-old male Wistar rats (Charles River Japan, Atsugi, Japan) were used for the present study. All animals were kept in specific pathogen-free conditions at the Nagasaki University Animal Center and allowed free access to food and tap water. They were orally treated with a mixture of CT (C:T=5:2) (Ajinomoto Co., Inc., Tokyo, Japan), which was suspended in 0.5% carboxymethyl cellulose solution (CMC) (FUJIFILM Wako Pure Chemical Corporation, Osaka, Japan) at 280mg/kg body weight/day. The non-treated control group received 0.5% CMC only. All treatments were

performed for five days before irradiation. Irradiated animal groups received whole-body irradiation using a Toshiba ISOVOLT TITAN32 X-ray, at 200kV at a dose rate of 0.5531Gy/min. A single dose of 2 or 5 Gy was administered. Non-irradiated groups (0 h or 0 d) were not irradiated, but were otherwise handled identically. This experimental protocol was approved by the Institutional Animal Care and Use Committee at Nagasaki University Animal Center (protocol No. #1606161315). This study protocol adhered to the ARRIVE guidelines.

## 2.2. Survival rate

The body weight was measured, and the survival of the CT-treated and control rats were determined by observations every 24 h for 28 days after 5 Gy irradiation. The rate of change of body weight and survival rate were compared between post-irradiation and pre-irradiation conditions.

## 2.3. Histopathologic examination

All animals were sacrificed by deep anesthesia at each time point (3 h, 6 h, 24 h (1 d), 48 h (2 d), 72 h (3 d), and 168 h (7 d)) after irradiation. Each jejunum and spine, including bone marrow, was resected, and immersed in neutral-buffered formalin, and routinely embedded in paraffin blocks. Spines were decalcified in EDTA for 20-30d after fixation. Sections were used for counting the number of mitotic figures and apoptotic cells with hematoxylin and eosin (H&E) stain,

immunohistochemistry, and TUNEL method.

Mucosa length, defined as the length from the apex of the brush border to the base of the crypt in the jejunum, and crypt depth (along the long axis of the elliptical crypt) were measured in H&E-stained section using a 100× magnification captured with light microscopy and a digital camera system (Keyence BZ-9000E, Keyence Co., Osaka Japan). The length of more than five random mucosa or crypt were measured, and the rate of the measured length of mucosa or crypt after irradiation was averaged per animal. Scoring of apoptotic and mitotic figures in the jejunum was restricted to good longitudinal sections of the crypt, in which the base of the crypt was aligned with all other crypt bases, indicating the crypt lumen. More than 30 longitudinal crypt sections were selected per animal, and apoptotic and mitotic cells were scored in each crypt in H&E-stained sections at 400× magnification by light microscopy, as described previously (Matsuu-Matsuyama et al., 2010). Bone marrow cells were counted in five areas per animal in H&E-stained sections at 200× magnification captured with light microscopy and a digital camera system (Nikon Camera Control Unit DS-L2, Nikon Co., Tokyo, Japan), and the measurements were averaged per animal. To assess the blood component, blood samples were collected from hearts of rats under deep anesthesia. Blood was collected from CT pre-treated rats and control rats 3 and 7 days after 5 Gy irradiation. Blood samples were also collected from non-irradiated CT pre-treated rats and control rats. Analysis of the number of red blood cells (RBC), white blood cells (WBC), and platelets (PLT) was performed in

LSI Medience Corporation (Tokyo, Japan).

#### 2.4. Immunohistochemistry

Immunohistochemical staining was performed for Ki-67 and cleaved caspase-3. Slides were stained as described previously (Matsuu-Matsuyama et al., 2010). Anti-rat Ki-67 monoclonal antibody (MIB-5) (Agilent Dako, CA, USA) and cleaved caspase-3 antibody (Cell Signaling Technology Inc., MA, USA) were used. The secondary antibody, LSAB-2 system–HRP for use on rat specimens (Agilent Dako, CA, USA), was used according to the manufacturer's instructions. Cells showing immunoreactivity for Ki-67 and cleaved caspase-3 were counted in more than 30 crypts and 50 villi of the jejunum per rat at 400× magnification using light microscopy. The cleaved caspase-3 positive bone marrow cells were counted in five or six areas from four rats in every group at 400× magnification captured with light microscopy and a digital camera system (Nikon Camera Control Unit DS-L2).

#### 2.5. TUNEL method

Apoptosis was confirmed using a TUNEL technique (Apoptag Peroxidase *In Situ* Apoptosis Detection Kit, EMD Millipore Co., CA, USA) that detects apoptosis-associated DNA fragmentation by labeling the 3'-OH termini with digoxigenin nucleotides using terminal deoxynucleotidyl

transferase. Slides were stained as described previously (Matsuu-Matsuyama et al., 2010). TUNEL positive cells were counted in more than 30 crypts and 50 villi of the jejunum per rat at 400× magnification using light microscopy. TUNEL positive bone marrow cells were counted in five or six areas per rat at 400× magnification captured with light microscopy and a digital camera system (Nikon Camera Control Unit DS-L2).

## 2.6. Statistics

A Wilcoxon test was employed for Kaplan-Meier survival analysis. The rate of change of the mucosal and crypt length, the number of bone marrow cells, and the values of RBC, WBC, and PLT were expressed as the means  $\pm$  SEM of results obtained from three to six animals per data point. The number of apoptotic cells, TUNEL, cleaved caspase-3, mitotic cells, and Ki-67 positive cells were expressed as the means  $\pm$  SEM of results obtained from pooled data from three to six animals per data point.

Differences between CT-treated and control groups were examined using Mann-Whitney *U* test. Statistical analyses were conducted using SAS statistical software (SAS Institute Inc., NA, USA) and Bell Curve for Excel (Social Survey Research Information Co., Ltd., Tokyo, Japan). *p* values less than 0.05 were considered statistically significant.

### 3. Results

#### 3.1. Survival rate and alterations of body weight

A total of 45 animals, including CT-treated (n=23) and control (n=22) groups, were analyzed. Body weight changes and survival rates of CT pre-treated rats and control rats are shown in Fig. 1. Body weight changes in the CT pre-treated group was significantly higher than that of the control group at 10, 12, 14, and 28 days after 5 Gy irradiation (Fig. 1A). The survival rate of CT pre-treated rats increased compared to that of control rats (78.3% vs. 54.5%,  $p=0.0434$ ) (Fig. 1B).

#### 3.2. Histopathology of the jejunum

For histopathology, a total of 129 animals, including CT-treated (n=64) and control (n=65) groups, were analyzed. Figure 2 shows the rate of mucosa and crypt length changes after 5 Gy irradiation. The mucosa length of the control group at 3 d was  $85.5\pm 4\%$  lower than that at 0 d, but results in the CT group were  $98.4\pm 3.8\%$  lower than that at 0 d. The mucosa length of controls at 7 d was  $119.5\pm 3\%$  greater than at 0 d, while results of the CT group were  $134.5\pm 3.7\%$  greater than that at 0 d. Mucosa length significantly differed between control and CT groups at 3 and 7 d (Fig. 2A). At 3 d, the crypt length increased by  $132.1\pm 3.7\%$  and  $147.5\pm 5.1\%$  compared to 0 d in control and CT groups, respectively. Crypt length differed significantly between control and CT groups at 3 d after irradiation (Fig. 2B). At 2 Gy, the rate of change of the mucosal and crypt length were lower

compared to observations at 5 Gy, there was no significant difference in mucosal and crypt length between control and CT groups (Suppl. Fig. 1). The pre-treatment of CT suppressed mucosal length decrease, while increasing crypt length after 5 Gy irradiation.

Figure 3 shows the number of apoptotic figures per crypt detected by H&E staining, and the number of TUNEL positive cells and cleaved caspase-3 positive cells per jejunal crypt and villi after 5 Gy irradiation. Apoptotic cells significantly decreased in the CT-pretreated group at 3, 6, 24, and 72 h compared to the control group after 5 Gy irradiation (Fig. 3A). CT-pretreatment significantly decreased the number of TUNEL positive cells in crypts at 3, 72, and 168 h compared to the control group after irradiation (Fig. 3B). Cleaved caspase-3 positive cells in crypts in the CT-treatment group significantly decreased at 3 and 6 h compared to the control group (Fig. 3C). In the mesenchymal cells of the villi, CT-pretreatment significantly decreased the number of TUNEL positive cells at 72 h compared to controls after irradiation. The number of cleaved caspase-3 positive cells decreased at 3 h (Fig. 3D, E). At 2 Gy, the number of apoptotic figures and TUNEL positive cells per crypt in the CT-treatment group decreased at 3, 6, and 24 h compared to the control group after irradiation (Suppl. Fig. 2A, B). In villi, the number of TUNEL positive cells in the CT-treatment group was decreased at 24 h compared to the control group (Suppl. Fig. 2C).

Figure 4 shows the number of mitotic cells per crypt detected by H&E staining, and the number of Ki-67 positive cells per crypt and mesenchymal cells of villi after 5 Gy irradiation.

CT-pretreatment significantly increased the number of mitotic cells in the jejunal crypt at 24 h after 5 Gy irradiation (Fig. 4A). The number of Ki-67 positive cells was significantly higher in crypts and villi in the non-irradiated CT-treated group compared to the control group (0 h). Further, CT-pretreatment significantly increased Ki-67 positive cells in crypts at 3, 6, 24, 72, and 168 h compared to the control group after 5 Gy irradiation (Fig. 4B). In villi, CT-pretreatment significantly increased Ki-67 positive cells at 168 h compared to the control group after 5 Gy irradiation (Fig. 4C). At 2 Gy, CT-pretreatment significantly increased mitotic cells in jejunal crypts at 6 and 168 h (Suppl.Fig. 3A). The number of Ki-67 positive cells was significantly higher in the CT-treated group compared to the control group at 0, 6, 24, 72, and 168 h (Suppl. Fig. 3B). In mesenchymal cells, CT-pretreatment significantly increased the number of Ki-67 positive cells at 3 and 6 h after 2 Gy irradiation (Suppl. Fig. 3C).

### 3.3. Histopathology of bone marrow

To examine the effect of CT-pretreatment on survival rate, blood and bone marrow were investigated by histological examination. Table 1 shows the results of RBC, WBC, and PLT levels after 5 Gy irradiation. The number of RBCs in both groups decreased at 7 d after irradiation. The number of WBCs in both groups decreased dramatically at 3 d, and this decrease continued until 7 d post-irradiation. The number of PLTs in both groups also decreased at 7 d after irradiation. There

was no difference in the number of RBCs and PLTs between control and CT-treatment groups at 3 and 7 d after irradiation. The number of WBCs was slightly higher in the CT-treatment group compared to the control group at 7 d post-irradiation, but not significantly. Figure 5 shows the morphological changes of the bone marrow and the number of bone marrow cells after irradiation. Bone marrow cells decreased dramatically at 3 d, and there were few bone marrow cells in both groups. However, the bone marrow cells of the CT pre-treatment group appeared at 7 d, while bone marrow cells of the CT-treated group was significantly higher compared to control rats at 7 d after irradiation. Megakaryocyte cells decreased gradually until 7 d post-irradiation in both groups. There was no significant difference between the CT-treatment group and the control group at each time point (data not shown).

Figure 6 shows the number of TUNEL and cleaved caspase-3 positive bone marrow cells after 5 Gy irradiation. In the CT-treated group, the number of TUNEL positive cells and cleaved caspase-3 positive cells significantly decreased after 5 Gy irradiation at 6 h and 3 h respectively (Fig.6A, B).

#### **4. Discussion**

The protective effect of CT was evaluated by analyzing the survival rate and acute radiation injury of bone marrow and the small intestine of rats exposed to whole-body radiation. CT pre-treatment significantly improved weight loss and survival rate of rats after whole-body

irradiation (5 Gy). Bone marrow cells and small intestinal crypt cells, which rapidly proliferate, are the most sensitive to radiation, and radiation-induced apoptosis is the primary cause of damage to the small intestine and bone marrow (Singh et al., 2017; Potten 2004). In this study, the protective effects of CT pre-treatment to protect against mucosa length shortening and increase the crypt length became clear after irradiation. CT could significantly reduce apoptotic cells, TUNEL positive cells, and cleaved caspase-3 positive cells in jejunal crypt cells after irradiation. In the mesenchymal cells of villi, CT-pretreatment could suppress TUNEL positive cells only at 72 h and cleaved caspase-3 at 3 h. Since the number of TUNEL positive cells and cleaved caspase-3 in the CT-treated group are higher than the control group at 6 h, the suppression effect of CT in mesenchymal cells of villi may be lower than that in crypt cells until 24 h. The difference in the number of apoptotic cells, TUNEL positive cells, and cleaved caspase-3 positive cells may reflect the time lag of caspase activation, apoptotic body processing, and degradation, as caspase-3 was activated earlier in the apoptotic process than DNA cleavage and cell fragmentation. It has been reported that a delayed increase in ROS after 5 Gy external irradiation induces serious DNA damage in a rat thyroid cell line. Pre- and post-administration of the antioxidant *N*-acetyl-L-Cysteine (NAC), a glutathione precursor, could suppress micronuclei induced by delayed ROS elevation (Kurashige et al., 2017). In this study, apoptosis induced in crypt and mesenchymal cells in jejunum of rats after 24 h may be attributed to delayed ROS elevation after 5 Gy irradiation, while CT pre-treatment may reduce apoptosis after 24

h by suppressing delayed ROS elevation, in a similar manner to NAC. CT pre-treatment significantly increased proliferation in jejunum crypt cells at each time point upon irradiation, while in mesenchymal cells of the villi, CT significantly increased proliferation a specified period after irradiation in response to apoptosis suppression after 24 h. Decreased radiation-induced apoptosis and proliferation activation of crypt and mesenchymal cells in CT-treated rats may reflect improved villi and crypt length post-irradiation.

Decreased RBC, WBC, and PLT numbers were not significantly different between the control and CT group post-irradiation. However, the number of bone marrow cells increased at 7 d in CT pre-treated rats. CT pre-treatment significantly reduced the number of apoptotic cells and cleaved caspase-3 positive cells in bone marrow. CT pre-treatment suppressed radiation-induced apoptosis in bone marrow, which may reflect improved bone marrow functionality post-irradiation. CT pre-treatment rescued bone marrow cells from apoptosis, this may reflect an improved survival rate post-irradiation. We have previously reported that whole-body X irradiation evokes stimulation of autonomic nervous function and severe intestinal injury, resulting in appetite loss and weight loss (Matsuu et al., 2005). CT protected against radiation-induced apoptosis and activated proliferation in the small intestine and bone marrow of CT pre-treated rats, exhibiting improved body weight and survival rate.

It has been reported that oral administration of CT increased GSH synthesis and that CT intake

inhibited intense exercise-induced inflammation (Kurihara et al., 2007; Tanaka et al., 2015). Research indicates that cystine suppressed IL-6 production and improved survival rates in a lipopolysaccharide (LPS)-induced sepsis mouse model, and enhanced production of IL-10 by monocytes may be involved in the anti-inflammatory response (Banerjee et al., 2012). It has been reported that redox buffer systems including small molecules (*e.g.* GSH/GSSG, cysteine/cystine) and proteins (*e.g.* thioredoxin) are employed for thiol-based redox homeostasis, which is essential for controlling cellular functions, including gene expression, cell cycle progression, and apoptosis (Tang et al., 2019). Furthermore, it has been reported that CT administration improves survival after gut ischemia-reperfusion in mice, and jejunal GSSG, cysteine and glutamic acid levels is higher in the CT than in the vehicle group after reperfusion (Miyakuni et al., 2018). It is conceivable that the protective effects of CT treatment against radiation-induced apoptosis in the jejunum and bone marrow is due to anti-oxidative effects through GSH synthesis. It is reported that ROS-regulated double strand breaks regulate ATM and p53, which in turn mediate the MAPK family (p38, ERK, and JNK) and regulate, inhibit, or promote oxidative stress (Jin et al., 2015). It has been reported that caffeic acid phenyl ester (CAPE), which is a potent anti-inflammatory agent with the ability to eliminate free radicals, attenuates ionizing radiation-induced intestinal injury through modulation of oxidative stress, apoptosis, and p38 MAPK, in a similar manner to NAC in rats (Jin et al., 2015). It is possible that CT protects against radiation-induced apoptosis through actions similar to CAPE and

NAC.

The aminothiols compound, amifostine (WR-2721, *S*-2-[3-aminopropylamino]ethylphosphorothioic acid), is a chemical radioprotector administered prior to radiotherapy or chemotherapy treatment in certain cancers to selectively reduce normal tissue damage (Brizel et al., 2000; Kouvaris et al., 2007; Ormsby et al., 2014; Yuhas and Storer, 1969). This drug was approved by the Food and Drug Administration to reduce nephrotoxicity from chemotherapy containing cisplatin and to decrease xerostomia caused due to radiation therapy (Sasse et al., 2006; Singh and Seed, 2019). The cytoprotective mechanism of amifostine involves free-radical scavenging, DNA protection and repair acceleration, and induction of cellular hypoxia (Kouvaris et al., 2007; Singh and Seed, 2019). It has been reported that amifostine can protect from apoptosis after high doses of radiation in mouse spleen and bone marrow (Ormsby et al., 2014). However, it has also been reported that amifostine exerts side effects such as hypotension, nausea, vomiting, a metallic taste during infusion, and occasional allergic reactions including rash, fever, and anaphylactic shock (Kouvaris et al., 2007). Amifostine is usually administered intravenously during radiation therapy (Kouvaris et al., 2007; Singh and Seed, 2019). CT is commercially available and can be easily administered orally in its powder form. A recent study reported that CT is safe for colorectal cancer patients receiving postsurgical adjuvant capecitabine therapy and tended to reduce the incidence rate of diarrhea and hand-foot syndrome (Hamaguchi et al., 2019). CT pretreatment

potentially prevents intestinal acute radiation injury during clinical radiotherapy for malignancies. Further studies are required to elucidate the mechanism by which CT protects against radiation-induced damage.

## **5. Conclusions**

Our results suggest that CT pre-treatment improved weight loss and the survival rate of rats. Additionally, CT exerts a protective effect against acute radiation-induced injury in rat jejunum and bone marrow cells through inhibition of apoptosis and cell proliferation acceleration. CT is commercially available and can be easily administered orally in its powder form. CT pretreatment potentially reduces damage to the gastrointestinal tract during abdominal radiation therapy for malignant tumors.

### **Figure legends**

**Fig.1.** Body weight changes observed in control and CT-pretreated groups after 5 Gy irradiation (A).

The data are expressed as means  $\pm$  SEM. n=8-22 (Control group) and n=14-23 (CT group). The survival curves of control and CT pre-treated groups after irradiation (B). n=22 (Control group) and n=23 (CT group) \* $p$ <0.05 vs control group.

**Fig.2.** Histological sections of the jejunum in control and CT-pretreated groups after 5 Gy irradiation

subjected to hematoxylin and eosin staining ( $\times 100$ ). The rate of mucosa (A) and crypt (B) length after 5 Gy irradiation. The data are expressed as means  $\pm$  SEM of four to six rats per data point.

\* $p$ <0.05 vs. control group.

**Fig.3.** The number of apoptotic cells per crypt after 5 Gy irradiation (A). The number of TUNEL

positive cells per crypt (B) and villi (D) after irradiation. The number of cleaved caspase-3 positive cells per crypt (C) and villi (E) after irradiation. The data are expressed as means  $\pm$  SEM of

n=125-262 crypts and n=188-266 villi from four rats. \* $p$ <0.05, \*\* $p$ <0.01 and \*\*\* $p$ <0.001 vs. control group.

**Fig.4.** The number of mitotic cells per crypt after 5 Gy irradiation (A). The number of Ki-67 positive cells per crypt (B) and villi (C) after irradiation. The data are expressed as means  $\pm$  SEM of n=125-244 crypts and n=200-215 villi from four rats. \* $p$ <0.05, \*\* $p$ <0.01 and \*\*\* $p$ <0.001 vs. control group.

**Fig.5.** Histologic sections of the bone marrow in control and CT-pretreated groups at 3 and 7 d after 5 Gy irradiation subjected to hematoxylin and eosin staining ( $\times 200$ ). Mk: megakaryocyte. The number of bone marrow cells per area. The data are expressed as means  $\pm$  SEM of four to six rats per data point. \* $p$ <0.05 vs. control group.

**Fig.6.** TUNEL and cleaved caspase-3 positive bone marrow cells after 5 Gy irradiation ( $\times 400$ ). The number of TUNEL positive cells per area after 5 Gy irradiation (A). The number of cleaved caspase-3 positive cells per area after 5 Gy irradiation (B). The data are expressed as means  $\pm$  SEM of 23-26 area from four rats. \* $p$ <0.05, \*\* $p$ <0.01 and \*\*\* $p$ <0.001 vs. control group.

**Suppl. Fig.1.** Histological sections of the jejunum in control and CT-pretreated groups after 5 Gy irradiation subjected to hematoxylin and eosin staining ( $\times 100$ ). The rate of mucosa (A) and crypt (B) length after 2 Gy irradiation. The data are expressed as means  $\pm$  SEM of three to five rats per data point.

**Suppl. Fig.2.** The number of apoptotic cells per crypt after 2 Gy irradiation (A). The number of TUNEL positive cells per crypt (B) and villi (C) after 2 Gy irradiation. The data are expressed as

means  $\pm$  SEM of 153-252 crypts and 297-494 villi from three to five rats. \* $p$ <0.05, \*\* $p$ <0.01 and \*\*\* $p$ <0.001 vs. control group.

**Suppl. Fig.3.** The number of mitotic cells per crypt after 2 Gy irradiation (A). The number of Ki-67 positive cells per crypt (B) and villi (C) after 2 Gy irradiation. The data are expressed as means  $\pm$  SEM of  $n=92-213$  crypts and  $n=130-215$  villi from three to five rats. \* $p$ <0.05, \*\* $p$ <0.01 and \*\*\* $p$ <0.001 vs. control group.

**Table 1**

Changes observed in red blood cells (RBC), white blood cells (WBC), and platelets numbers in CT pre-treated and control groups after 5 Gy irradiation.

	Time (d)	Control	n	CT	n
RBC ( $\times 10^4/\mu\text{l}$ )	0	733.5 $\pm$ 8.6	6	750 $\pm$ 22.9	5
	3	742.6 $\pm$ 23.8	5	732.3 $\pm$ 24	4
	7	670.2 $\pm$ 19	5	676.5 $\pm$ 4.7	6
WBC (/ $\mu\text{l}$ )	0	4700 $\pm$ 407.4	6	4120 $\pm$ 592.8	5
	3	400 $\pm$ 137.8	5	350 $\pm$ 86.6	4
	7	180 $\pm$ 20	5	250 $\pm$ 22.4	6
PLT ( $\times 10^4/\mu\text{l}$ )	0	99.3 $\pm$ 5.3	6	100.1 $\pm$ 9.1	5
	3	98.9 $\pm$ 3.9	4	87 $\pm$ 6.7	4
	7	4.6 $\pm$ 0.4	5	7.5 $\pm$ 1.5	3

Values are expressed as mean  $\pm$  SEM; WBC, white blood cells, RBC, Red blood cells, PLT, platelets
